The Korringa ratio, $\mathcal{K}$, obtained by taking an appropriate combination of the Knight shift and nuclear spin-lattice relaxation time, is calculated at finite temperature, T , in the three-dimensional electron gas model, including the electron-electron interaction, U , and non-magnetic impurity scatterings. $\mathcal{K}$ varies in a simple way with respect to U and T ; it decreases as U is increased but increases as T is raised. However, $\mathcal{K}$ varies in a slightly more complicated way with respect to the impurity scatterings; as the scattering rate is increased, $\mathcal{K}$ increases for small U and low T , but decreases for large U or high T regime. This calls for a more careful analysis when one attempts to estimate the Stoner factor from $\mathcal{K}$.

I. INTRODUCTION

The Korringa ratio, $\mathcal{K}$, given by $\mathcal{K} = 1/(T_1 T K^2)$, where T_1 is the nuclear spin-lattice relaxation time, K the Knight shift, and T is the temperature, is a useful concept [1], in that when $\mathcal{K}$ of a material is larger (smaller) than unity, it is interpreted as a strong indication that the material is antiferromagnetically (ferromagnetically) correlated. Moriya, some forty years ago, showed that $\mathcal{K}$ is decreased when there is electron-electron interaction, U , in a three-dimensional (3D) free electron gas [2]. Underlying physics is that K^2 increases more rapidly than $1/T_1 T$ for a ferromagnetically correlated system as U is increased. It was later extended to include the non-magnetic impurity scattering effects by Shastry and Abrahams [3]. They showed that disorder enhances the Korringa ratio so that the impurity effects should be included in addition to the electron-electron interaction when one analyzes the ratio, eg, when one wants to estimate the Stoner factor of a material from $\mathcal{K}$. These calculations were done at zero temperature. Since experiments are performed at finite temperature, we wish to extend their calculations to the finite temperature, and understand how $\mathcal{K}$ is changed as the temperature, T , the electron-electron interaction, U , and the impurity scattering rate, $1/\tau$, are varied.

K and $1/T_1$, which determine $\mathcal{K}$, can be expressed in terms of the spin susceptibility, $\chi(\mathbf{q}, \omega)$, of the conduction electrons. Fulde and Luther calculated the impurity effects on the spin susceptibility of almost ferromagnetic metals by including isotropic non-magnetic impurity scatterings and Dirac δ -function electron-electron interaction at zero temperature, in the small frequency and the small wavevector limit [4]. Their result was utilized by Shastry and Abrahams to calculate $\mathcal{K}$ of almost ferromagnetic dirty metals. In the present work, we reformulate the spin susceptibility with the Matsubara Green's function to consider the finite temperature effects on the Korringa ratio at the presence of the electron-electron interaction and impurity scatterings. The calculated K , T_1 , and $\mathcal{K}$ agree in most cases with those of Shastry and Abrahams: both K and $1/T_1 T$ increase when U or $1/\tau$ is increased, and $\mathcal{K}$ decreases as U is increased. One interesting observation, different from their results, is that $\mathcal{K}$ increases as $1/\tau$ is increased only when *both* U and T are small. When U is comparable with U_{cr} , or T is with ϵ_F , $\mathcal{K}$ decreases as $1/\tau$ is raised. U_{cr} is the critical value of the electron-electron interaction at which the ferromagnetic instability occurs, and ϵ_F is the Fermi energy. Consequently, $\mathcal{K}$ vs. U curves for several different $1/\tau$ values, at a fixed T , cross each other. These crosses also occur in $\mathcal{K}$ vs. T at a given U among different values of $1/\tau$. It has been believed, since the Shastry and Abrahams work, that the impurity scatterings enhance $\mathcal{K}$ while the electron-electron interaction suppresses it. The present result that impurity scatterings can enhance or suppress depending on U or T requires that the above interpretation should be modified. This calls for a more careful analysis of experimental data when one wishes to estimate the strength of ferromagnetic correlation of a material.

The remainder of the present paper is organized as follows: In Sec. II, we present the Matsubara formalism to include the electron-electron interaction and impurity scatterings in calculating $\chi(\mathbf{q}, \omega)$ at finite temperature. This was carried out in the Matsubara frequency and then analytically continued to the real frequency. In Sec. III, K , $1/T_1 T$, and $\mathcal{K}$ are calculated by numerically integrating the obtained equations, as U , $1/\tau$, and T are varied. These results are compared with the free electron gas model as a reference, and with previously reported calculations. Finally, Sec. IV is for the summary and concluding remarks.

II. FORMALISM

The Korringa ratio is obtained from the Knight shift and nuclear spin-lattice relaxation time as $\mathcal{K} = 1/(T_1 T K^2)$, and K and $1/T_1$ are given in terms of the spin susceptibility as

$$K \propto \lim_{\substack{\mathbf{q} \rightarrow 0 \\ \omega \rightarrow 0}} \text{Re} \chi(\mathbf{q}, \omega),$$

$$\frac{1}{T_1 T} \propto \lim_{\omega \rightarrow 0} \sum_{\mathbf{q}} \frac{1}{\omega} \text{Im} \chi(\mathbf{q}, \omega). \quad (1)$$

Calculating the Korringa ratio, therefore, amounts to calculation of $\chi(\mathbf{q}, \omega)$ including the electron-electron interaction and the impurity scatterings at finite temperature. This can most conveniently be done in terms of the Matsubara Green's function in the imaginary frequency to obtain $\chi(\mathbf{q}, i\omega)$. It is then analytically continued to yield $\chi(\mathbf{q}, \omega)$ in the real frequency by substituting $i\omega \rightarrow \omega + i\delta$, where δ is a positive infinitesimal. We, therefore, reformulate the Fulde and Luther result with the Matsubara method for spin susceptibility and construct K and $(T_1 T)^{-1}$. The spin susceptibility including the vertex corrections from the Coulomb interaction and electron-impurity scatterings can be expressed in terms of the Feynman diagram as in Fig. 1(a). Here, the solid lines denote the renormalized electron Green's function $G(\mathbf{k}, ip)$, and Γ denotes the vertex function, where ip and $i\omega$ are, respectively, the fermion and boson Matsubara frequencies, and $\mathbf{k}$ and $\mathbf{q}$ are the corresponding wavevectors. Γ includes both the impurity and the Coulomb interaction as shown in Fig. 1(b), but G does not include the renormalization from the electron-electron interaction as in the previous works [4,3]. The neglect of U in calculating G may be justified because Schrieffer and Berk showed that this model reproduces the long wave length static susceptibility which would be obtained from a more complete calculation including the renormalizations due to U [5].

Γ , represented in Fig. 1(b), can be written as

$$\Gamma(\mathbf{q}, ip, i\omega) = 1 - \frac{U}{\beta} \sum_{ip'} \sum_{\mathbf{k}'} G(\mathbf{k}', ip') G(\mathbf{k}' + \mathbf{q}, ip' + i\omega) \Gamma(\mathbf{q}, ip', i\omega)$$

$$+ \frac{1}{2\pi N \tau} \sum_{\mathbf{k}'} G(\mathbf{k}', ip) G(\mathbf{k}' + \mathbf{q}, ip + i\omega) \Gamma(\mathbf{q}, ip, i\omega). \quad (2)$$

Here, $\beta = 1/k_B T$, N the single-spin density of states (DOS) at the Fermi level, and $G(\mathbf{k}, ip) = 1/[ip + \frac{i}{2\tau} \text{sgn}(p) - \xi_{\mathbf{k}}]$, where $\text{sgn}(p)$ is 1 if p is positive or zero and is -1 otherwise, and $\xi_{\mathbf{k}}$ is energy measured from the Fermi surface, or $\xi_{\mathbf{k}} = \hbar^2 \mathbf{k}^2 / 2m - \epsilon_F$. χ can be written as in Ref. [4] in Matsubara form as

$$\chi(\mathbf{q}, i\omega) = -\mu_B^2 \frac{2}{\beta} \sum_{ip} \sum_{\mathbf{k}} G(\mathbf{k}, ip) G(\mathbf{k} + \mathbf{q}, ip + i\omega) \Gamma(\mathbf{q}, ip, i\omega) \quad (3)$$

$$= 2\mu_B^2 N \frac{\chi_{\text{imp}}(\mathbf{q}, i\omega)}{1 - NU \chi_{\text{imp}}(\mathbf{q}, i\omega)},$$

where

$$\chi_{\text{imp}}(\mathbf{q}, i\omega) = -\frac{2\pi}{\beta} \sum_{ip} \frac{J(\mathbf{q}, ip, i\omega)}{1 - \frac{1}{\tau} J(\mathbf{q}, ip, i\omega)} \quad (4)$$

and

$$J(\mathbf{q}, ip, i\omega) = \frac{1}{2\pi N} \sum_{\mathbf{k}} G(\mathbf{k}, ip) G(\mathbf{k} + \mathbf{q}, ip + i\omega) \quad (5)$$

$$= \frac{im^2}{4\pi^2 N q} \ln \left[\frac{\text{sgn}(\tilde{p}) \sqrt{i\tilde{p} + \mu} + \text{sgn}(\tilde{p} + \tilde{\omega}) \sqrt{i(\tilde{p} + \tilde{\omega}) + \mu} + \sqrt{\epsilon_q}}{\text{sgn}(\tilde{p}) \sqrt{i\tilde{p} + \mu} + \text{sgn}(\tilde{p} + \tilde{\omega}) \sqrt{i(\tilde{p} + \tilde{\omega}) + \mu} - \sqrt{\epsilon_q}} \right].$$

Here, we put $k_B = \hbar = 1$, μ_B the Bohr magneton, m the electron mass, $\epsilon_q = q^2 / 2m$, $i\tilde{p} = ip + \frac{i}{2\tau} \text{sgn}(p)$, and μ is the chemical potential. In order to obtain χ in the real frequency, analytic continuation of $i\omega \rightarrow \omega + i\delta$ is performed after the frequency summation. The frequency summation can be done in complex plane using contour integral, where summation is replaced by integrals over branch cut lines [6]. Then, χ_{imp} can be written as

$$\chi_{\text{imp}}(q, \omega) = -i \int_{-\infty}^{\infty} d\varepsilon \left\{ \left[n_F(\varepsilon + \omega) - n_F(\varepsilon) \right] F\left(\varepsilon - \frac{i}{2\tau}, \varepsilon + \omega + \frac{i}{2\tau}\right) + n_F(\varepsilon) F\left(\varepsilon + \frac{i}{2\tau}, \varepsilon + \omega + \frac{i}{2\tau}\right) - n_F(\varepsilon + \omega) F\left(\varepsilon - \frac{i}{2\tau}, \varepsilon + \omega - \frac{i}{2\tau}\right) \right\}, \quad (6)$$

where we introduce for convenience an expression

$$F\left(\varepsilon \pm \frac{i}{2\tau}, \varepsilon + \omega \pm \frac{i}{2\tau}\right) = \frac{J\left(\varepsilon \pm \frac{i}{2\tau}, \varepsilon + \omega \pm \frac{i}{2\tau}\right)}{1 - \frac{1}{\tau} J\left(\varepsilon \pm \frac{i}{2\tau}, \varepsilon + \omega \pm \frac{i}{2\tau}\right)}, \quad (7)$$

and

$$J\left(\varepsilon \pm \frac{i}{2\tau}, \varepsilon + \omega \pm \frac{i}{2\tau}\right) = \frac{im^2}{4\pi^2 Nq} \ln \left(\frac{\pm \sqrt{\varepsilon + \mu \pm \frac{i}{2\tau}} \pm \sqrt{\varepsilon + \omega + \mu \pm \frac{i}{2\tau}} + \sqrt{\epsilon_q}}{\pm \sqrt{\varepsilon + \mu \pm \frac{i}{2\tau}} \pm \sqrt{\varepsilon + \omega + \mu \pm \frac{i}{2\tau}} - \sqrt{\epsilon_q}} \right). \quad (8)$$

Here, $n_F(\epsilon) = 1/[1 + \exp(\beta\epsilon)]$ is the Fermi distribution function.

Now we can express K and $(T_1 T)^{-1}$ with this susceptibility, through taking its real and imaginary parts. $(T_1 T)^{-1}$ can be written as

$$\frac{1}{T_1 T} \propto \frac{\mu_B^2 N}{\pi^2} \int_0^\infty dq q^2 \frac{\partial \chi_{\text{imp}2} / \partial \omega(q, \omega \rightarrow 0)}{[1 - NU \chi_{\text{imp}1}(q, \omega \rightarrow 0)]^2} \quad (9)$$

where χ_2 and $\chi_{\text{imp}2}$ denote the imaginary parts of χ and χ_{imp} , respectively. $\chi_{\text{imp}1}$ and $\chi_{\text{imp}2}$ in Eq. (9) can be written as

$$\chi_{\text{imp}1}(t) = \int_{-\infty}^{\infty} dx \left(\frac{1}{1 + e^{Bx}} \right) \text{Im} \left\{ \frac{J(x + i\eta, x + i\eta)}{1 - \eta J(x + i\eta, x + i\eta)} \right\}, \quad (10)$$

$$\frac{\partial \chi_{\text{imp}2}(t)}{\partial \omega} = \frac{1}{2\epsilon_F} \int_{-\infty}^{\infty} dx \frac{-B e^{Bx}}{(1 + e^{Bx})^2} \text{Re} \left[\left\{ \frac{J(x + i\eta, x + i\eta)}{1 - \eta J(x + i\eta, x + i\eta)} \right\} - \left\{ \frac{J(x - i\eta, x + i\eta)}{1 - \eta J(x - i\eta, x + i\eta)} \right\} \right], \quad (11)$$

where $B = \beta\epsilon_F$, $\eta = (2\tau\epsilon_F)^{-1}$, $M = \mu/\epsilon_F$, $t = q/k_F$, $x = \varepsilon/\epsilon_F$, and

$$J(x \pm i\eta, x + i\eta) = \frac{i}{2t} \ln \left(\frac{\pm \sqrt{x + M \pm i\eta} + \sqrt{x + M + i\eta} + t}{\pm \sqrt{x + M \pm i\eta} + \sqrt{x + M + i\eta} - t} \right). \quad (12)$$

In the same way, K is written as

$$\begin{aligned} K &\propto \lim_{\substack{\omega \rightarrow 0 \\ \mathbf{q} \rightarrow 0}} \chi_1(\mathbf{q}, \omega) \\ &= 2\mu_B^2 N \text{Re} \left[\frac{\chi_{\text{imp}1}(0, 0)}{1 - NU \chi_{\text{imp}1}(0, 0)} \right], \end{aligned} \quad (13)$$

where $\chi_{\text{imp}1}(0, 0)$ is given from Eq. (10) by

$$\chi_{\text{imp}1}(0, 0) = \int_{-\infty}^{\infty} dx \frac{1}{1 + e^{Bx}} \text{Re} \left[\frac{1}{2\sqrt{x + M + i\eta} - i\eta} \right]. \quad (14)$$

ηJ in the denominator in Eqs. (10) and (11), and $i\eta$ outside the square root in Eq. (14) are from the impurity vertex correction. These vertex parts from Eqs. (10) and (14) cause the crosses between the curves of $\mathcal{K}$ with T and U .

III. RESULTS

Let us first consider the free electron gas model for a reference before we present the calculations for ferromagnetically correlated dirty metals. For a 3D free electron gas model, it is simple to calculate the static susceptibility $\chi(\mathbf{q}, \omega \rightarrow 0)$ as a function of T [7]. From χ , K and $(T_1 T)^{-1}$ are given as

$$K \propto \sqrt{\frac{\mu}{\epsilon_F}} \left[1 - \frac{\pi^2}{24} \left(\frac{T}{\mu} \right)^2 - \dots \right],$$

$$\frac{1}{T_1 T} \propto 2\pi\mu_B^2 N^2 \frac{T}{\epsilon_F} \ln(1 + e^{\mu/T}), \quad (15)$$

where the chemical potential μ is given by

$$\mu \approx \begin{cases} \epsilon_F \left[1 - \frac{\pi^2}{12} \left(\frac{T}{\epsilon_F} \right)^2 \right], & \text{for } T \ll \epsilon_F, \\ T \ln \left[\frac{4}{3\sqrt{\pi}} \left(\frac{\epsilon_F}{T} \right)^{3/2} \right], & \text{for } T \gg \epsilon_F. \end{cases} \quad (16)$$

We, therefore, have

$$\frac{K}{K_0} \approx \begin{cases} 1 - \frac{\pi^2}{12} \left(\frac{T}{\epsilon_F} \right)^2, & \text{for } T \ll \epsilon_F, \\ 1/T, & \text{for } T \gg \epsilon_F, \end{cases} \quad (17)$$

and

$$\frac{(T_1 T)^{-1}}{(T_1 T)_0^{-1}} \approx \begin{cases} 1 - \frac{\pi^2}{12} \left(\frac{T}{\epsilon_F} \right)^2, & \text{for } T \ll \epsilon_F, \\ 1/\sqrt{T}, & \text{for } T \gg \epsilon_F, \end{cases} \quad (18)$$

where $K_0 = 2\mu_B^2 N$ and $(T_1 T)_0^{-1} = 2\pi\mu_B^2 N^2$ denote, respectively, their zero temperature values at $U = 1/\tau = 0$. From these elementary considerations, we see that

$$\mathcal{K} \propto \begin{cases} 1 + \frac{\pi^2}{12} \left(\frac{T}{\epsilon_F} \right)^2, & \text{for } T \ll \epsilon_F, \\ T^{3/2}, & \text{for } T \gg \epsilon_F. \end{cases} \quad (19)$$

Introducing impurity scatterings and electron-electron interaction does not alter in an essential way the K , $1/T_1 T$ and $\mathcal{K}$ vs. T behavior of Eqs. (17), (18), and (19), but change their T dependence by altering the three coefficients: (a) the value at $T = 0$, (b) the low T coefficient proportional to T^2 (Lorentzian width), and (c) the high T coefficient, as shown in Figs. 2 and 3. K/K_0 as a function of T for a set of $\eta = 1/(2\tau\epsilon_F)$ and NU , where $NU_{cr} = 1$ is the critical value at which the ferromagnetic instability occurs at $T = 0$ and $\eta = 0$, are shown in Fig. 2(a). Both NU and η enhance K in agreement with Shastry and Abrahams. The low temperature coefficients of K/K_0 vs. T can be calculated analytically as functions of NU and η : (a) The $T = 0$ peak is given by $a/(1 - aNU)$, and (b) the low T Lorentzian width by $2\sqrt{1 - aNU}/\sqrt{b}$, where $a = 1 + \frac{\pi}{4}\eta - \frac{3}{8}\eta^2$ and $b = \frac{\pi^2}{12}[1 - (1 + \frac{\pi}{4})\eta + \frac{1}{4}(3 + \pi + \frac{\pi^2}{4})\eta^2]$. The numerical calculations agree perfectly well with the analytically obtained asymptotic behavior. In Fig. 2(b), $(T_1 T)^{-1}/(T_1 T)_0^{-1}$ as a function of T are shown for a set of η and NU . Their general behavior is almost the same with that of K/K_0 . In Ref. [8] and [9], $(T_1 T)^{-1}$ measured as a function of T is almost constant above T_c in the fullerene superconductors. It is difficult, however, to compare the present results with experimental observations because the lattice constant changes from the thermal expansion. The lattice constant expansion affects the DOS and, consequently, K and $1/T_1 T$.

In Fig. 3(a), we show $\mathcal{K}$ as a function of T for a set of η and NU . One can see that (a) the $T = 0$ value is suppressed by NU , but, by η , it is increased for small U and decreased for large U , ($\mathcal{K} = 1$ for $T = U = \eta = 0$.) (b) the low T coefficient is nearly independent of NU and η , and (c) the high T coefficient proportional to $T^{3/2}$ is reduced as η becomes larger. Above changes cause the $\mathcal{K}$ vs. T curves cross each other as can be seen in Fig. 4. These crosses do not appear if we neglect the impurity vertex correction in $\chi_{\text{imp}1}$, that is, if we neglect the $1/\tau$ term in the denominator of $\chi_{\text{imp}1}$, and their origin is this impurity vertex correction, as will be discussed in more detail below. Now, let us consider the $T = 0$ limit case, which can directly be compared with Shastry and Abrahams. In Fig. 3(b), we show $\mathcal{K}$ as a function of NU for $\eta = 10^{-4}$, 0.05, and 0.1 at $T = 0$. The three $\mathcal{K}$ vs. NU curves cross each other as NU is increased, as in Fig. (a) discussed above. These crosses did not occur in Shastry and Abrahams, who neglected the impurity vertex correction in $\chi_{\text{imp}1}$. At $T = 0$, and for small q and ω , the impurity enhanced susceptibility, χ_{imp} , can be expanded by integrating Eq. (6) as,

$$\chi_{\text{imp}}(q, \omega) \approx \chi_{\text{imp}}^{(0)}(q, \omega) \frac{D_0 q^2}{D_0 q^2 - i\omega}, \quad (20)$$

where the diffusion constant is given by $D_0 = \tau v_F^2/3$, and $\chi_{\text{imp}}^{(0)}(0, 0) = \chi_{\text{imp}}(0, 0) = \chi_{\text{imp}1}(0, 0) = 1 + \frac{\pi}{4}\eta + \frac{1}{8}\eta^2$, up to the order of η^2 . The $\pi\eta/4$ in $\chi_{\text{imp}}^{(0)}$ comes from the impurity vertex correction in the $\omega = q = 0$ limit, and $\eta^2/8$ from

the self-energy correction due to impurity scatterings in the renormalized Green's functions. Shastry and Abrahams neglected the impurity vertex corrections in calculating $\chi_{\text{imp}}(q, \omega = 0)$, and found that $\chi_{\text{imp}}^{(0)}(0, 0) \approx 1 + \eta^2/8$ in agreement with the present result. These two terms enhance $\chi_{\text{imp1}}(0, 0)$ compared with the free electron value of 1. Because $\chi_{\text{imp1}}(q, 0)$ is multiplied by NU in the denominator when calculating K or $1/(T_1 T)$ as in Eqs. (9) or (13), the effects of U are stronger for larger η . Consequently, $\mathcal{K}$ decreases faster for larger η as NU is increased. This, together with the fact that $\mathcal{K}$ is larger for larger η at $U = 0$, causes the crosses among the curves of $\mathcal{K}$ vs. NU as shown in Fig. 3(b). Since the $\pi\eta/4$ term in $\chi_{\text{imp1}}(0, 0)$ is dominant contribution from the impurity scatterings compared with $\eta^2/8$, these crosses do not occur without the impurity vertex correction. It should be interesting if this prediction can be confirmed by experiments.

IV. SUMMARY AND CONCLUDING REMARKS

In this paper, we studied the Korringa ratio $\mathcal{K} = 1/(T_1 T K^2)$, Knight shift K , and nuclear spin-lattice relaxation time T_1 of ferromagnetically correlated impure metals at finite temperature. They were calculated from the spin susceptibility including the self-energy correction due to the impurity scatterings, and the vertex correction due to the δ -function electron-electron interaction and impurity scatterings. The spin susceptibility was formulated with Matsubara Green's function to consider the finite temperature effects and analytically continued to the real frequency. The K and $(T_1 T)^{-1}$ decrease with T , but $\mathcal{K}$ increases as T is raised because K^2 decreases more rapidly than $(T_1 T)^{-1}$ with T . Also, K and $(T_1 T)^{-1}$ increase as U or η is increased, and $\mathcal{K}$ decreases as U is increased.

The conventional interpretation of the Korringa ratio, as mentioned in Introduction, is that when $\mathcal{K}$ of a material is larger (smaller) than unity, it implies that the material is antiferromagnetically (ferromagnetically) correlated. The Shastry and Abrahams contribution is that $\mathcal{K}$ is increased by the non-magnetic impurity scatterings, so that $\mathcal{K}$ of ferromagnetically correlated dirty metals, where $\mathcal{K}$ is suppressed by the ferromagnetic correlation but increased by the impurity scatterings, can be close to 1, just like the free electron case. This means that one should be careful in extracting the strength of ferromagnetic correlation from the Korringa ratio.

Our observation in the present work is that the Korringa ratio is increased by the non-magnetic impurity scatterings when *both* U and T are small, but $\mathcal{K}$ is decreased by the impurity scatterings when U is comparable with U_{cr} or T is comparable with ϵ_F . This implies that $\mathcal{K}$ is enhanced by the impurity scatterings only for weakly ferromagnetic dirty metals at low T , but suppressed when U or T is large. This causes the crosses among the $\mathcal{K}$ vs. NU curves for the different impurity scattering rates $1/\tau$ in the present calculations. The crosses also occur in $\mathcal{K}$ vs. T at a given U among different values of $1/\tau$. Those crosses are caused by the impurity vertex correction in $\chi_{\text{imp1}}(0, 0)$, which was neglected in the previous calculations. The present exact numerical calculations within the finite temperature extension of the Fulde and Luther formulation, shown in Fig. 3, confirm that above behavior is due to the impurity vertex corrections. This observation requires that the interpretation according to Shastry and Abrahams should be modified, and one should do more careful analysis in estimating the strength of ferromagnetic correlation of impure materials from the Korringa ratio.

FIG. 1. (a) is the Feynman diagram of the spin susceptibility, and (b) is for the renormalized vertex Γ including the impurity and Coulomb interactions. The solid line indicates the electron Green's function, the dashed line the electron-electron interaction, and the dashed line with a cross stands for the impurity scatterings. ip and $i\omega$ are, respectively, the fermion and boson Matsubara frequencies, and k, q are corresponding wave vectors.

FIG. 2. (a) is the normalized Knight shift K/K_0 vs. the reduced temperature, T/ϵ_F , and (b) is $(T_1 T)^{-1}/(T_1 T)_0^{-1}$ vs. T/ϵ_F . K_0 and $(T_1 T)_0^{-1}$ are, respectively, the zero temperature values of K and $(T_1 T)^{-1}$ at $T = U = \eta = 0$ limit. $NU = 0, 0.4, 0.8$ from bottom to top and $\epsilon_F = 0.25$ eV. K/K_0 and $(T_1 T)^{-1}/(T_1 T)_0^{-1}$ decrease more rapidly with T when NU or η is large.

FIG. 3. (a) is the Korrington ratio $\mathcal{K}$ vs. T/ϵ_F , and (b) is $\mathcal{K}$ vs. NU at $T = 0$ limit. $\mathcal{K}=1$ in the $T = U = \eta = 0$ limit. $\epsilon_F = 0.25$ eV, and $NU = 0, 0.4, 0.8$ from bottom to top for Fig. (a). The crosses among the curves for different η occur at lower T as NU is increased, implying that in $\mathcal{K}$ vs. NU crosses occur at lower NU when T is increased. Fig. (b) can be compared with Ref. 3, where there are no crosses among different η values.
